ABSTRACT
With explosive growth of Android malware and due to the severity of its damages to smart phone users, the detection of Android malware has become increasingly important in cybersecurity. The increasing sophistication of Android malware calls for new defensive techniques that are capable against novel threats and harder to evade. In this paper, to detect Android malware, instead of using Application Programming Interface (API) calls only, we further analyze the different relationships between them and create higher-level semantics which require more efforts for attackers to evade the detection. We represent the Android applications (apps), related APIs, and their rich relationships as a structured heterogeneous information network (HIN). Then we use a meta-path based approach to characterize the semantic relatedness of apps and APIs. We use each meta-path to formulate a similarity measure over Android apps, and aggregate different similarities using multi-kernel learning. Then each meta-path is automatically weighted by the learning algorithm to make predictions. To the best of our knowledge, this is the first work to use structured HIN for Android malware detection. Comprehensive experiments on real sample collections from Comodo Cloud Security Center are conducted to compare various malware detection approaches. Promising experimental results demonstrate that our developed system HinDroid outperforms other alternative Android malware detection techniques.

1 INTRODUCTION
Smart phones have been widely used in people’s daily life, such as online banking, automated home control, and entertainment. Due to the mobility and ever expanding capabilities, the use of smart phones has experienced an exponential growth rate in recent years. It is estimated that 77.7% of all devices connected to the Internet will be smart phones in 2019 [13], leaving PCs falling behind at 4.8%. Android, as an open source and customizable operating system for smartphones, is currently dominating the smartphone market by 82.8% [4]. However, due to its large market share and open source ecosystem of development, Android attracts not only the developers for producing legitimate Android applications (apps), but also attackers to disseminate malware (malicious software) that deliberately fulfills the harmful intent to the smartphone users. Because of the lack of trustworthiness review methods, developers can upload their Android apps including repackaged apps, ransomware [5], or trojans to the market easily in even Google’s official Android market. The presence of other third-party Android markets (e.g., Opera Mobile Store, Wandoujia) makes this problem worse. Many examples of Android malware have already been released in the market (e.g., Geinimi, DriodKungfu and Lotoor) [31] which posed serious threats to the smart phone users, such as stealing user credentials, auto-dialing premium numbers, and sending SMS messages without user’s concern [9]. According to Symantec’s Internet Security Threat Report [28], one in every five Android apps (nearly one million total) were actually malware. To protect legitimate users from the attacks of Android malware, currently, the major defense is mobile security products, such as Norton, Lookout and Comodo Mobile Security, which mainly use the signature-based method to recognize threats. However, attackers can easily use techniques, such as code obfuscation and repackaging, to evade the detection. The increasing sophistication of Android malware calls for new defensive techniques that are robust and capable of protecting users against novel threats.

To be more resilient against the Android malware’s evasion tactics, in this paper, instead of using Application Programming Interface (API) calls only, we further analyze the relationships among them, e.g., whether the extracted API calls belong to the same code block [13], are with the same package name, or use the same invoke method, etc. Relations between APIs and apps and different types relations among apps themselves can introduce higher-level semantics and require more efforts for attackers to evade the detection. To represent the rich semantics of relationships, we first introduces a structured heterogeneous information network (HIN) [11, 18] representation to depict apps and APIs. Then we use meta-path [19] to incorporate higher-level semantics to build up the semantic relatedness of apps. In this way, a similarity between two

apps can not only capture whether they are using the same sets of APIs but also capture whether the APIs have similar usage patterns, such as in the same package. Since there can be multiple meta-paths to define different similarities and we want to incorporate all useful meta-paths and discard useless ones, we propose to use a multi-kernel learning algorithm [23] to automatically learn the weights of different similarities from data. In short, our developed system called HinDroid has the following major traits:

- **Novel structural feature representation:** Instead of using API calls only, we further analyze the relationships among them. Based on the extracted features, the Android apps will be represented by a structural heterogeneous information network (HIN), and a meta-path based approach will be used to link the apps. In this way, the detection of a malicious Android app is an aggregation of different similarities defined by different meta-paths. This is much more complicated than traditional approaches and is more difficult and costly to be evaded.

- **Multi-kernel learning for HIN:** HIN is a conceptual representation of many other kinds of data, e.g., social networks, scholarly networks, knowledge graphs, etc. The similarities defined by different meta-paths can be used to make decisions in an aggregated way. In this paper, we propose a multi-kernel learning to learn from data to determine the importance of different meta-paths. This is a very natural way to handle HIN based similarities but to our best knowledge is a first attempt.

- **A practical developed system for real industry application:** We develop a practical system HinDroid for automatic Android malware detection and provide a comprehensive experimental study based on the real sample collection from Comodo Cloud Security Center, which demonstrates the effectiveness and efficiency of our developed system. HinDroid has already been incorporated into the scanning tool of Comodo Mobile Security product. The system has been deployed and tested based on the real daily sample collection (over 15,000 Android apps per day) for around half a year (about 2,700,000 Android apps in total).

The remainder of this paper is organized as follows. Section 2 presents the overview of our system architecture. Section 3 introduces our proposed method in detail. In Section 4, based on the real sample collection from Comodo Cloud Security Center, we systematically evaluate the performance of our developed system HinDroid which integrates our proposed method, in comparison with other alternative detection methods and some of the popular Mobile Security products (e.g., Lookout, Norton Mobile Security). Section 5 presents the details of system development and operation. Section 6 discusses the related work. Finally, Section 7 concludes.

2 SYSTEM OVERVIEW

In this section, we present our system overview with preliminaries.

2.1 Preliminaries

Unlike traditional desktop based Portable Executable (PE) files, Android app is compiled and packaged in a single archive file (with an .apk suffix) that includes the app code (.dex file), resources, assets, and manifest file. Dex (i.e., Dalvik executable) is a file format which contains compiled code written for Android and can be interpreted by the DalvikVM [2], but it is unreadable. In order to analyze the Android apps, we need to convert the dex file to a readable format. **Smali** is an assembler/disassembler for the dex format [2], which provides us readable code in smali language. **Smali code** is the intermediate but interpreted code between Java and DalvikVM [3]. Listing 1 shows a segment of the converted smali code from a ransomware “Locker.apk” (MD5: f836f5c6267f13bf9f6109ab8d79175) that will lock smart phone user’s screen (shown in Figure 1(b)) after the installation (shown in Figure 1(a)). If the smart phone is infected by this malware, the victim is demanded to pay a ransom to attackers to unlock the smart phone.

![Figure 1: Screen shots of the ransomware “Locker.apk”](image)

14 .end method

2.2 System Architecture

In this paper, to analyzed the collected Android apps, we first unzip each Android Application Package (APK) to get the dex file, and then generate the small codes by decompiling the dex file. By analyzing the small codes, a complete Android API call list will be extracted, and then the relationships among the extracted API calls will be further analyzed. Figure 2 shows the system overview of our developed Android malware detection system HinDroid, which consists of the following five major components.

- **Unzzipper and Decomplier:** The APKTool [1] is used to unzzip the APKs and decompile the dex files to small codes.

- **Feature Extractor:** It automatically extracts the API calls from the decompiled small codes. The API calls extracted from the smali codes will be converted to a group of global integer IDs which represents the static execution sequence of the corresponding API calls. Based on the extracted API calls, the relationships among them will be further analyzed, i.e., whether
3 PROPOSED METHOD

In this section, we introduce the detailed approaches of how we represent the Android apps, and how to solve the classification problem based on the representation.

### 3.1 Feature Extraction

#### 3.1.1 API Call Extraction

API calls are used by the Android apps in order to access operating system functionality and system resources. Therefore, they can be used as representations of the behaviors of an Android app. In order to extract the API calls, the Android app is first unzipped to provide the dex file, and then the dex file is further decompiled into smali codes using a well-known reverse engineering tool APKTool [1]. The converted smali codes can then be parsed for API call extraction. For example, in the smali code segment as shown in Listing 1, the API calls of "Ljava/lang/Runtime; → getRuntime() Ljava/lang/Runtime", "Ljava/lang/Runtime; → exec (Ljava/lang/String;) Ljava/lang/Process" and "Ljava/lang/Process; → getInputStream() Ljava/io/InputStream" will be extracted.

#### 3.1.2 Relationship Analysis among the Extracted API Calls

Although API calls can be used to represent the behaviors of an Android app, the relations among them can imply important information for malware detection. For example, as the aforementioned ransomware "Locker.apk", the API calls of "Ljava/io/FileOutputStream → write", "Ljava/io/IOException → printStackTrace", and "Ljava/lang/System → load" together in the method of "loadLibs" in the converted smali code indicate this ransomware intends to write malicious code into system kernel. Though it may be common to use them individually in benign apps, they three together in the same method of the converted smali code rarely appear in benign files. Thus, the relationship that these three API calls co-exist in the same method in the converted smali code is an important information for such ransomware detection. To describe such relationships, we define a code block as the code between a pair of "method" and "endmethod" in the smali file, which reflects the structural information among the API calls. After the extraction of the API calls from the converted smali codes, to represent such kind of relationship R1, we generate the API-CodeBlock matrix B where each element $b_{ij} = r_{ij} \in \{0, 1\}$ denotes whether this pair of API calls belong to the same code block.

Except for that whether the API calls co-exist in the same code block, we find that API calls which belong to the same package always show similar intent. For example, the API calls in the package of "Lorg/apache/http/HttpRequest" are related to Internet connection. The API calls co-appear in the same package indicate strong relations among them. To represent such kind of relationship R2, we generate the API-Package matrix P where each element $p_{ij} = r_{ij} \in \{0, 1\}$ denotes if a pair of API calls belong to the same package. As the example shown in Listing 1, both API "Ljava/lang/Runtime; → getRuntime() Ljava/lang/Runtime" and API "Ljava/lang/Runtime; → exec (Ljava/lang/String;) Ljava/lang/Process" are from the same package "Ljava/lang/Runtime", so the element representing the relation of these two APIs in the matrix will be set to 1.

In the smali code, there are five different methods to invoke an API call [2]: (1) invoke-static: invokes a static method with parameters; (2) invoke-virtual: invokes a virtual method with parameters; (3) invoke-direct: invokes a method with parameters without the virtual method resolution; (4) invoke-super: invokes the virtual method of the immediate parent class; and (5) invoke-interface: invokes an interface method. Since the same invoke
method can show the common properties of the API calls (like the words have the same part of speech), two API calls using the same invoke method may indicate specifically implicit relations among them. To represent this kind of relationship $R_3$, we generate the \textit{API-InvokeMethod} matrix $I$ where each element $I_{ij} = 1$ indicates whether a pair of API calls use the same invoke method. To further illustrate, as shown in Listing 1, API calls “$\text{Ljava/lang/Runtime;} \rightarrow \text{exec (Ljava/lang/String;)}$” and “$\text{Ljava/lang/Process;} \rightarrow \text{getInputStream()}$” both use the invoke-virtual method, so the element denoting the relation of these two APIs in the matrix will be set to 1.

A summary of the description of different relations and their elements in the relation matrices is shown in Table 1. The relationships among the extracted API calls (i.e., whether they belong to the same code block, are with the same package name, or use the same invoke method) create a higher-level representation than a simple list of API calls and require more efforts for attackers to evade the detection (e.g., it may result in execution collapse if the attackers add several non-associated API calls in the same code block).

### 3.2 HIN Construction

Given the analysis of rich relationship types of API calls for Android apps, it is important to model them in a proper way so that different relations can be better and easier handled. When we apply machine learning algorithms, it is also better to distinguish different types of relations. Thus, in this section, we introduce how to use heterogeneous information network to represent the Android apps by using the features (including API calls and the relationships among them) extracted above. We first introduce some concepts related to heterogeneous information networks as follow.

\textbf{Definition 3.1.} [18] A \textit{heterogeneous information network} (HIN) is a graph $G = (V, E)$ with an entity type mapping $\phi: V \rightarrow \mathcal{A}$ and a relation type mapping $\psi: E \rightarrow \mathcal{R}$, where $V$ denotes the entity set and $E$ denotes the link set, $\mathcal{A}$ denotes the entity type set and $\mathcal{R}$ denotes the relation type set, and the number of entity types $|\mathcal{A}| > 1$ or the number of relation types $|\mathcal{R}| > 1$. The \textit{network schema} for network $G$, denoted as $\mathcal{T}_G = (\mathcal{A}, \mathcal{R})$, is a graph with nodes as entity types from $\mathcal{A}$ and edges as relation types from $\mathcal{R}$.

HIN not only provides the network structure of the data associations, but also provides a high-level abstraction of the categorical association. In our application for Android malware detection, we have two entity types, i.e., Android app and API call. There are four types of relations, e.g., app containing API call, API calls in the same code block, API calls with the same package name, and API calls with the same invoke type. The different types of entities and different relations of APIs motivate us to use a machine-readable representation to enrich the semantics of similarities among APIs. Meta-path [19] was used in the concept of HIN to formulate the semantics of higher-order relationships among entities. Here we follow this concept and extend it to our HinDroid framework.

\textbf{Definition 3.2.} [19] A meta-path $P$ is a path defined on the graph of network schema $\mathcal{T}_G = (\mathcal{A}, \mathcal{R})$, and is denoted in the form of $A_1 \rightarrow A_2 \rightarrow \ldots \rightarrow A_L$, which defines a composite relation $R = R_1 \cdot R_2 \cdot \ldots \cdot R_L$ between types $A_1$ and $A_L$, where $\cdot$ denotes relation composition operator, and $L$ is the length of $P$.

A typical meta-path for apps is $\text{App} \xrightarrow{\text{contains}} \text{API} \xrightarrow{\text{contains}^{-1}} \text{App}$. This means that we want to connect two apps through the path containing the same API over the HIN. There can be multiple API calls satisfying this meta-path constraint. Thus, we use the following commuting matrix [19] to give a general form to compute entity similarities using a particular meta-path.

\textbf{Definition 3.3.} [19] Given a network $G = (V, E)$ and its network schema $\mathcal{T}_G = (\mathcal{A}, \mathcal{R})$, a \textit{commuting matrix} $M_P$ for a meta-path $P = (A_1 - A_2 - \ldots - A_L)$ is defined as $M_P = G_{A_1,A_2}G_{A_2,A_3}\ldots G_{A_{L-1},A_L}$, where $G_{A_i,A_j}$ is the adjacency matrix between types $A_i$ and $A_j$, $M_P(i,j)$ represents the number of path instances between entities $x_i \in A_i$ and $y_j \in A_j$ under the meta-path $P$.

For example, the adjacency matrix between apps and API calls is $G_{\text{App,API}}$. Then the commuting matrix of apps computed using the meta-path $\text{App} \xrightarrow{\text{contains}} \text{API} \xrightarrow{\text{contains}^{-1}} \text{App}$, which is $A A^T$. If we denote $a_{ij}$ as the $i$th row of the matrix $A$, then the similarity between app $i$ and $j$ is given by $a_{ij}^2$, which is simply the dot product of two feature vectors. Each feature vector can be regarded as using a bag-of-APIs to represent an app.

More complicated similarities can be defined by commuting matrix based on the meta-path. Here we only consider the symmetric meta-path since we only focus on apps similarity. For example, we can define a meta-path $\text{App} \xrightarrow{\text{contains}} \text{API} \xrightarrow{\text{same code block}} \text{API} \xrightarrow{\text{contains}^{-1}} \text{App}$. This means that we compute the similarity between two apps not only considering API calls inside, but also considering the type of API calls inside. In this example, we use the bag-of-APIs in the same code block as features, and then use the dot product to compute the similarities.

### 3.3 Multi-Kernel Learning

Given a network schema with different types of entities and relations, we can enumerate a lot of meta-paths. However, not all of the meta-paths are useful for the particular Android malware detection problem. Thus, an intuitive way is to combine different meta-paths. Since we are using a supervised learning approach to learn from examples of Android malware, and HIN can naturally
provide us different similarities with different semantic meanings, here we propose to use a multi-kernel learning algorithm to automatically incorporate different similarities and determine the weight for each meta-path when classifying apps.

Suppose we have \( K \) meta-paths \(~P_k, \ k = 1, \ldots, K\). We can compute the corresponding commuting matrices \( M_{P_k}, \ k = 1, \ldots, K\), where \( M_{P_k} \) is regarded as a kernel. If the commuting matrix is not a kernel (not positive semi-definite, PSD), we simply use the trick to remove the negative eigenvalues of the commuting matrix. Following \[10, 16, 23\], we use the linear combination of kernels to form a new kernel:

\[
M = \sum_{k=1}^{K} \beta_k M_{P_k},
\]

where the weights \( \beta_k \geq 0 \) and satisfy \( \sum_{k=1}^{K} \beta_k = 1 \).

To learn the weight of each meta-path, we assume we have a set of labeled data \( \{x_i, y_i\}_{i=1}^{N} \), where \( x_i \) is the app (here we can regard \( x_i \) as an ID), and \( y_i \in \{+1, -1\} \) is the label. Then we use the \( p \)-norm multi-kernel learning framework \[23\] with following objective function to learn the parameters:

\[
\min_{\mathbf{w}>0, \xi_i \geq 0, \beta_k \geq 0} \frac{1}{2} \sum_k ||\mathbf{w}_k||^2 / \beta_k + C \sum_i \xi_i + \frac{\lambda}{2} \left( \sum_k \beta_k \right)^{2/p},
\]

\[
s.t. \quad y_i \left( \sum_k \mathbf{w}_k^T \phi_k(x_i) + b \right) \geq 1 - \xi_i, \tag{2}
\]

where for each kernel we learn a parameter vector \( \mathbf{w}_k \). For each data \( \{x_i, y_i\} \), the slack parameter \( \xi_i \) is introduced to allow mis-classification. \( \phi_k(x) \) is the nonlinear mapping of features in the Hilbert space that defines the kernel, where \( \phi_k(x) = M_{P_k}^{i,j} \). Then by applying the representation theorem, we have \( \mathbf{w}_k = \sum_i \alpha_i \phi_k(x_i) \). \( \alpha_i \) can be solved using the dual formulation, and non-zero \( \alpha_i \)'s lead to the support vectors.

In multi-kernel learning framework, another set of parameters besides \( \mathbf{w}_k \) is \( \beta_k \). Here the \( p \)-norm \( \left( \sum_k \beta_k \right)^{2/p} \) is used to regularize the optimization of \( \beta_k \)'s. Empirically we found 2-norm is the best, and apply it to our problem throughout the paper. After the optimization, the weights \( \beta_k \)'s are optimized to reveal the importance of the meta-paths serving as kernels. For a new app \( x \) coming, \( \sum_k \mathbf{w}_k \phi_k(x) + b \) is used to evaluate whether it is malicious or not.

4 EXPERIMENTAL RESULTS AND ANALYSIS

In this section, we show four sets of experimental studies using real sample collections obtained from Comodo Cloud Security Center to fully evaluate the performance of our developed Android malware detection system HinDroid: (1) In the first set of experiments, we evaluate the detection performance of our proposed method; (2) In the second set of experiments, we evaluate our developed system HinDroid which integrates our proposed method by comparisons with other alternative classification methods in Android malware detection; (3) In the third set of experiments, we compare the detection performance of HinDroid with other commercial mobile security products; (5) In the last set of experiments, we systematically evaluate our developed system HinDroid in real industry for Android malware detection.

4.1 Experimental Setup

We obtain two datasets from Comodo Cloud Security Center: (1) The first sample set includes recent collected Android apps (through January 30, 2017 to February 5, 2017), which contains 1,834 training Android apps (920 of them are benign apps, while the other 914 apps are malware including the families of Lotoor, RevMob, Fakegupdt, and GhostPush, etc.), and 500 testing samples (with the analysis by the anti-malware experts of Comodo Security Lab, 198 of them are labeled as benign and 302 of them are labeled as malicious). (2) The second dataset has larger sample collection containing 30,000 Android apps obtained within one month (January 2017), half of which are benign apps and the half are malicious apps. We evaluate the Android malware detection performance of different methods using the measures shown in Table 2.

4.2 Detection Performance Evaluation of the Proposed Method

In this set of experiments, based on the first sample set described in Section 4.1, resting on the 200 extracted API calls and the three different kinds of relationships generated among them (\( R1, R2, R3 \) as described in Section 3.1), we construct 16 meta-paths (shown in Table 3) and compare their detection performances by using Support Vector Machine (SVM). Table 1 gives the description of each matrix which forms different meta-paths. We also evaluate the combined similarity [25, 26] by selecting the meta-paths using Laplacian score [12]. We rank each meta-path using its Laplacian score. The order of the ranking is: \( PID12 \rightarrow PID16 \rightarrow PID6 \rightarrow PID3 \rightarrow PID5 \rightarrow PID1 \rightarrow PID9 \rightarrow PID2 \rightarrow PID8 \rightarrow PID7 \rightarrow PID13 \rightarrow PID14 \rightarrow PID15 \rightarrow PID10 \rightarrow PID4 \rightarrow PID1 \). We select the top five meta-paths (i.e., \( PID12, PID16, PID6, PID3, \) and \( PID5 \)) and use their Laplacian scores as the weights to construct a new kernel (i.e., \( PID17 \)) fed to the SVM. Similar to multi-kernel learning, if the similarity matrix is not PSD, we remove the negative eigenvalues following [26]. We also use these top five meta-paths as the kernels and apply multi-kernel learning (described in Section 3.3) for comparison (i.e., \( PID19 \)). Another set of comparison is using all the meta-paths (i.e., \( PID18 \) with combined similarity and \( PID20 \) by applying multi-kernel learning). The experimental results are shown in Table 3.

From Table 3 we can see that different meta-paths indeed show different detection performance. For example, some meta-paths,

Table 3: Detection performance evaluation

e.g., AA^T, ABA^T, and APBP^T A^T, perform well on the test set. Some other meta-paths do not perform well on their own, such as AIBPB^2 I^2 A^T, which may be because the semantics of the meta-path does not reflect the problem of Android malware detection well. However, when we combine these meta-paths to others, they still help to improve the classification results.

Laplacian score indeed helps us select some important meta-paths. For example, among PID12, PID16, PID6, PID3, and PID5, the meta-paths for PID6, PID3, and PID5 are very good. However, the weights used for combining the meta-paths are the Laplacian scores which may not be the best to reflect classification property. From the result we can see that “Combined-kernel (5)” for test set is with 91.20% detection accuracy and “Combined-kernel (16)” is 96.80%. This shows that by combining different meta-paths using Laplacian score, it can also improve the performance.

Finally, the method using multi-kernel learning successfully outperforms the single meta-paths and the unsupervised meta-path selection algorithm, i.e., Laplacian score. From the results we can see that, both “Multi-kernel (5)” over the five selected ones by Laplacian score and “Multi-kernel (16)” performed very well. To demonstrate the effectiveness of multi-kernel learning, we further show the correlation between the learned parameter βk weighting each meta-path in multi-kernel learning algorithm, shown in Eq. (1), and the actual performance of each meta-path in Table 3 and Figure 3. We can see that βk’s can successfully filter out the meta-paths that do not perform well on the malware prediction problem while maintaining the “good” meta-paths for final decision of malware detection.

Since HIN construction in our framework can be fully automated, the only parameter we need to tune is in multi-kernel learning. In this experiment, based on five-fold cross validation, we show the results using different values of the penalty parameter C ranging from 1 to 10^5. Figure 4 shows the stability of Hindroid with different parameters. From the figure, we can see that in a wide range of numbers, our algorithm is stable and not very sensitive to the penalty parameter. This indicates that for practical use, we can simply tune a parameter using some training data based on cross-validation, and apply that parameter to the test set without concerning the change of the parameter affecting the online performance.
4.3 Comparisons of HinDroid and other Alternative Detection Methods

In this set of experiments, based on the first sample set described in Section 4.1, we compare HinDroid (i.e., the system integrating multi-kernel learning based on all the constructed 16 meta-paths) with four other typical classification methods, i.e., Artificial Neural Network (ANN), Naïve Bayes (NB), Decision Tree (DT), and Support Vector Machine (SVM) based on the extracted API calls as well as feature engineering based on the discussion in Section 3.1. For ANN, we use 3 hidden layers (500 neurons in each hidden layer) and train the network using back propagation. The learning rate is set to 0.3 and the momentum is set as 0.5. For SVM, we use LibSVM in our experiment and the penalty is empirically set to be 1,000.

The experiment results are shown in Table 4. From the results we can see that feature engineering helps the performance of machine learning, since the rich semantics encoded in different types of relations can bring more information. However, the use of this information for traditional machine learning algorithms is simply flat features, i.e., concatenation of different features altogether. From Table 4, we can see that HinDroid further outperforms these alternative classification methods with feature engineering in Android malware detection. In Table 4, we also show detailed information of true-positive and false-positive numbers for different algorithms. It’s shown that our HinDroid algorithm can significantly reduce the numbers. To check whether the overall improvement is significant, we also run 30 random trials of training and testing examples to compare HinDroid and SVM with feature engineering, and the probability associated with a paired t-Test with a two-tailed distribution is 1.62 × 10^{-13}. This shows that HinDroid is significantly better than the best baseline method we compared.

The reason behind this is that, in HinDroid we use more expressive representation for the data, and build the connection between the higher-level semantics of the data and the final results. This again demonstrates that using HinDroid can reduce the work of feature engineering, and significantly improve the Android malware detection performance.

4.4 Comparisons of HinDroid and other Commercial Mobile Security Products

In this set of experiments, to evaluate the detection performance of HinDroid, based on the first sample set described in Section 4.1, we also compare it with some other popular commercial mobile security products (e.g., Clean Master (CM), Lookout and Norton Mobile Security). For the comparisons, we use all the latest versions of the mobile security products (i.e., Clean Master (CM): 2.08, Lookout: 10.9-7f33b3e, and Norton: 3.17.0.3205).

Table 5 shows different detection results from HinDroid and other mobile security products. From Table 5, we can see that HinDroid outperforms others in the detection of the most recent collected Android malware from different families (e.g., Lotoor, RevMob, and GhostPush, etc.). The success of HinDroid may lie in its novel higher-level semantic feature representations as well as the multi-kernel learning based on the constructed HIN in feature engineering. Besides, HinDroid also has high detection efficiency: the prediction of an Android app is around 3-5 seconds on average, including the feature extraction.

4.5 Evaluations Based on Large and Real Sample Collection from Industry

In this experiment, based on a real and larger data collection from Comodo Cloud Security Center (i.e., 30,000 Android apps obtained within one month (January 2017), half of which are benign apps and the half are malicious apps), we systematically evaluate the performance of our developed system HinDroid, including the detection effectiveness and scalability.
which contains over 15,000 unknown files per day. Note that Android malware techniques are constantly evolving and new of our developed system are dynamically changing to include newly the temporal trends of Android malware writing, the training sets malware samples are produced on a daily basis. To account for the daily sample collection from Comodo Cloud Security Center HinDroid has already been incorporated into the scanning tool of Comodo’s Mobile Security Product. By adopting the proposed methods, our developed system 5 SYSTEM DEPLOYMENT AND OPERATION

Figure 5 shows the overall and zoomed-in receiver operating characteristic (ROC) curves for this experiment based on the ten-fold cross validations. From Figure 5, we can see that HinDroid achieves an impressive 0.9833 TP rate at the 0.0087 FP rate while labeling the newly collected Android apps.

Figure 5: Left: ROC curve of HinDroid, Right: Zoomed-in.

We also further evaluate the training time of HinDroid with different sizes of the training data sets. Figure 7 shows the scalability of our proposed method. It is shown that similar to other kernel methods, the multi-kernel learning is quadratic to the number of data samples. When dealing with more data, approximation or parallel algorithms should be developed. However, as shown in Figure 6, for such Android malware detection problem, the need of more labels is not as important as the need of more expressive representations of data. Therefore, for practical use, our approach is still feasible.

Figure 6: Scalability evaluation of HinDroid

Figure 7: Comparisons when training data sizes vary

5 SYSTEM DEPLOYMENT AND OPERATION

By adopting the proposed methods, our developed system HinDroid has already been incorporated into the scanning tool of Comodo’s Mobile Security Product. HinDroid has been used to predict the daily sample collection from Comodo Cloud Security Center which contains over 15,000 unknown files per day. Note that Android malware techniques are constantly evolving and new malware samples are produced on a daily basis. To account for the temporal trends of Android malware writing, the training sets of our developed system are dynamically changing to include newly collected apps. Our system HinDroid has been deployed and tested based on the real daily sample collection for around half a year (about 2,700,000 Android apps in total have either been trained or tested).

For the development of the system, Comodo has spent over $250K, including hardware equipment and human resource investment. Due to the high detection efficiency and effectiveness, the developed system HinDroid can greatly save human labors and reduce the staff cost: over 50 anti-malware analysts at Comodo Cloud Security Center are utilizing the system on the daily basis. In practice, an anti-malware analyst has to spend at least 8 hours to manually analyze 40 Android apps for malware detection. Using the developed system HinDroid, the analysis of about 15,000 file samples can be performed within minutes with multiple servers. This would benefit over 10 million smart phone users of Comodo’s Mobile Security product.

6 RELATED WORK

In recent years, there have been research studies on developing intelligent Android malware detection systems using machine learning and data mining techniques [6–8, 29, 30]. DroidDolphin [30] used a dynamic analysis framework including DroidBox and APE to record thirteen activity features from the collected Android apps, and then applied Support Vector Machine (SVM) to build a malware prediction model. Crowdroid [6] also performed dynamic analysis for Android malware detection which extracted API system calls as the feature set for k-means clustering. CopperDroid [22], an automatic Virtual Machine Introspection (VMI) based dynamic analysis system, extracted operating system interactions (e.g., file and process creation), as well as intra- and inter-process communications (e.g., SMS reception) as the features to represent the behaviors of the Android apps. Though dynamic extraction is more resilient to low level obfuscation, it is computationally expensive to perform and requires simulation of user interactions. On the contrast, static analysis focuses on analyzing the internal components of an app without executing it. This makes it much cheaper to perform than dynamic analysis. DroidMat [29] performed static analysis on Android apps to extract API calls, permissions and intent messages as the input features for k-means clustering and finally k-NN classification. DroidMiner [32] also extracted API calls, but then transformed them into modalities for associative classifier. Peiravian and Zhu [15] analyzed Android apps creating a feature set consisting of API calls and permission requests that they then fed to SVM, Decision Tree, and ensemble classifiers. Due to its high efficiency in feature extraction, in this paper, we choose to use static analysis for feature representation of Android apps. We first extract API calls from the smali files. Different from the existing works [15, 29, 32], we then further analyze the relationships between them (i.e., whether the extracted API calls belong to the same smali code block, are with the same package names, or use the same invoke method). Based on these extracted features, the Android apps will be represented by a structured heterogeneous information network (HIN), and a meta-path based approach will be used to link the apps.

Heterogeneous information network has been proposed for several years. HIN is a conceptual representation of graph/network with different types of entities and relations [11, 18]. It has been

7 CONCLUSION

To combat the Android malware threats, in this paper, instead of using API calls only for feature representation, we further analyze the relationships among them, which create higher-level semantics and require more efforts for attackers to evade the detection. Based on the extracted features, we present a novel Android malware detection framework, HinDroid, which introduces a structured heterogeneous information network (HIN) representation of Android apps, and a meta-path based approach to link the apps. We use each meta-path to formulate a similarity measure over Android apps, and aggregate different similarities using multi-kernel learning. Then each meta-path is automatically weighted by the learning algorithm. To the best of our knowledge, this is the first work to use HIN representation for Android malware detection. A comprehensive experimental study on the real sample collections from Comodo Cloud Security Center is performed to compare various malware detection approaches. Promising experimental results demonstrate that HinDroid outperforms other alternative Android malware detection techniques as well as popular mobile security products. The system has already been incorporated into the scanning tool of Comodo Mobile Security product.
